Achieving effective, durable, and safe pain relief, especially in patients with chronic and/or severe pain conditions, can be a clinical challenge. For many types of pain, prescription opioids are among the most effective analgesics [Fine and Portenoy 2004]. However, there could be concerns about the development of opioid tolerance or adverse effects, and in some cases opioids seem to worsen pain (e.g., hyperalgesia) [Compton 2008; DuPen et al. 2007; Stein et al. 2003]. For certain difficult conditions, such as fibromyalgia or neuropathies, opioids alone are sometimes considered of limited effectiveness [Chou et al. 2009].

Healthcare providers interested in pain management must be alert to new or novel approaches that help to overcome deficiencies of opioids, such as treatment-limiting side effects, and as aids in relieving difficult-to-treat pain conditions. In this regard, there is a growing body of evidence suggesting potential benefits of opioid antagonists.

Opioid antagonists — in particular, naloxone and naltrexone — have been available and studied for decades as agents that displace opioid molecules from their neuroreceptors, and block opioids from attaching to and activating those receptors. Such qualities can be of important benefit, as short-acting antagonists like naloxone are used effectively to quickly reverse toxic effects of opioid overmedication or overdose.

Laboratory research and clinical trials have demonstrated the unexpected, paradoxical effects of opioid antagonists as adjuvants for enhancing rather than attenuating analgesic effects of opioids like morphine, oxycodone, and others. Further benefits of opioid antagonists, as monotherapy, for better managing certain chronic pain conditions also have been discovered.

This paper provides an overview of naloxone and naltrexone pharmacology, and briefly examines some of the theoretical found-
Opioid Antagonist Pharmacology

Opioid antagonists have been available for many decades and are well known for their applications in addiction treatment (naltrexone) and as an antidote for opioid overdose (naloxone). The first report of agents having opioid antagonist-like properties was in 1915, when N-allylnorcodeine was observed to block the respiratory-depressant effects of morphine and heroin. The opioid antagonist nalorphine was synthesized in the 1940s; however, it also had partial agonist activity and its unsettling effects on mood (causing dysphoria) discouraged widespread use for treating opioid intoxication or overdose [Gonzales and Brogden 1988; Zimmerman and Leander 1990].

In 1960, naloxone was synthesized as a more potent and less toxic antagonist than nalorphine. Naloxone produces no dysphoria but it has a short duration of action and poor oral bioavailability due to high first-pass hepatic metabolism; it is 15 times more potent by injection than by mouth. The need for a long-acting opioid antagonist as a treatment for addiction, by blocking the euphoric effects of illicit opioids for an extended period of time, motivated the development of naltrexone in 1963. This antagonist has reasonably good oral bioavailability, a long duration of action, and twice the potency of naloxone [see Table 1: Crabtree 1984; Gonzales and Brogden 1988; Reisine and Pasternak 1996].

The development of these agents was facilitated by the interesting fact that relatively minor structural changes could convert an opioid agonist drug into one with antagonist actions; that is, blocking various opioid receptors and preventing their activation. Thus, morphine was transformed into nalorphine, and oxymorphone into either naloxone or naltrexone. A more recent development, nalmefene, is a pure mu-receptor antagonist that is at least equipotent with naloxone but longer acting, with a duration of action between naloxone and naltrexone. Additional antagonists that are selectively active at other opioid receptors have been developed largely for experimental purposes [Barsan 1989; Reisine and Pasternak 1996; Zimmerman and Leander 1990].

Naloxone and naltrexone are the two opioid antagonists that have been most extensively studied and are commercially available today. They are FDA-approved for the treatment of alcoholism or opioid addiction (naltrexone; eg, Trexan®, Revia®, Depade®) or opioid overdose (naloxone; eg, Narcan®). A long-acting, high-dose depot form of naltrexone (Vivitrol®) for intramuscular injection also is approved for addiction therapy. These antagonists also are being
used or tested as ingredients in specially formulated opioid analgesics to deter their misuse or abuse (see Side Box).

As noted above, two important features distinguishing naloxone from naltrexone are the very limited oral bioavailability of naloxone and the extended action of naltrexone. Both, naltrexone and naloxone may interact with all classes of opioid receptors [Shader 2003] but they do so most strongly at mu-opioid receptors [Reisine and Pasternak 1996]. However, the typical naltrexone doses used for addiction therapy (50–100 mg/day orally) and naloxone dosing for reversing opioid overdose (0.4–1.0 mg/dose IV or IM) are, in most cases, different from the dosing protocols used in pain management applications (discussed below). In general, the literature refers to doses of antagonists, particularly naltrexone, in the 1 to 5 mg range as “low dose”; whereas, those less than 1 mg, in microgram amounts, are usually designated as “ultralow dose.”

Special Qualities of Opioid Antagonists

In an excellent review of the role opioid antagonists may play in pain management, Sloan and Hamann [2006] note that interest in this topic dates back to the 1950s. It was observed that low doses of the antagonist nalorphine had pain-relieving properties in humans comparable to low-dose morphine in some cases. It was suspected that a combined opioid agonist-plus-antagonist agent might offer significant pain-relief without the undesirable side effects of opioids alone. However, this line of research was not pursued until quite recently.

It was later discovered that naloxone had an analgesic effect at very low doses but no such effect at higher doses. For example, experiments in opioid-naive human subjects during the 1970s found that “low-dose” naloxone (up to 2 mg) had analgesic effects that were lacking at higher naloxone doses (eg, 7.5 mg and 10 mg) [Sloan and Hamann 2006]. The proposed neurobiological mechanisms behind this are complex and still being defined.

Studies in opioid-free animals have shown that, by causing a transient blockade of opioid receptors, low doses of antagonists stimulate increased production, or upregulation, of mu-opioid receptors in regions of the brain that control pain responses [references in Mannelli et al. 2006]. Therefore, it seems plausible that after antagonist effects wear off — which may take minutes or hours depending on the agent and dose — greater numbers of opioid receptors are available to bind with pain-relieving opioids in the circulatory system, whether externally administered (eg, morphine) or endogenous peptides (eg, endorphins). At the same time, it has been noted that the body responds to the temporary opioid-receptor blockade by producing substantially increased amounts of beneficial natural endorphins [NCI 2007; Smith et al 2007]. However, if the opioid-receptor blockade by antagonist is too extensive or continues too long, these pain relieving benefits are not realized, so the dose and half-life of the particular antagonist are critical factors.

Laboratory experiments further demonstrated that opioid antagonists may help to prevent the potential hyperalgesic (pain enhancing) and other negative effects of opioid pain relievers. At a cellular level, it is believed that exposure to opioid analogics at certain doses and for prolonged periods of time may lead to aberrant signaling patterns by opioid receptors. These pat-
terns can be reversed and restored to normal by the actions of opioid antagonists in very low concentrations [Sloan and Hamann 2006; Webster et al. 2006].

The ultimate effects of these mechanisms, demonstrated in animal studies and human trials, appears to be an enhancement by low- or ultralow-dose naloxone or naltrexone of opioid-agonist antinociceptive (pain relieving) efficacy. Along with this, tolerance to and physiologic dependency on opioid agonists, such as morphine and others, may be diminished [Crain and Shen 2000a]. Essentially, appropriately low doses of opioid antagonists have been postulated to “reset” the opioid-receptor system for a period of time [Loitman 2006], which seems analogous to how rebooting a malfunctioning computer clears memory, refreshes the software, and often restores normal function. The best type of antagonist, the optimal dose of it for achieving these effects, and the duration of effects have been explored by various investigators, as described below.

### Research on Naloxone in Pain Management

The traditional role of naloxone has been the complete reversal of opioid effects, particularly in cases of opioid overmedication or life-threatening overdose. However, the potentials of this agent in pain management have been described in a number of studies.

Loitman [2006] reported an interesting case series of 3 patients with intractable chronic pain — despite receiving large doses of strong opioids, other medications, and complementary procedures — who underwent a brief and temporary inpatient opioid-receptor reversal (that is, detoxification) procedure with intravenous naloxone (0.6–1.2 mg). This induced rapid withdrawal as the opioids were displaced from their receptors by the antagonist. Distressing withdrawal symptoms were ameliorated by sedation and, after a brief period of time (about 20 minutes), opioid pain relievers were readministered.

All patients responded very positively to the procedure, achieving much greater pain relief than before the brief detoxification and at significantly lower doses of opioid analgesics. Overall, Loitman noted that vastly improved pain relief was achieved in less than one hour on about one-third of the original opioid dose. Although exact mechanisms were unclear, the opioid receptors were thought to have been “reset” (as discussed above), overcoming prior opioid tolerance and/or hyperalgesia.

A number of clinical investigations have suggested potential benefits of ultralow-dose oral naloxone administration for postoperative pain:

- In patients treated with buprenorphine (a mixed agonist-antagonist opioid) postoperatively and experiencing breakthrough pain, the addition of oral ultralow-dose naloxone (0.08–0.4 mg, or 80–400 mcg*) provided effective and long-lasting analgesia (median 22 hrs) [Schmidt et al. 1985]. A more recently reported investigation, by La Vincente and colleagues [2008], also confirmed the enhancement of buprenorphine analgesia by ultralow-dose oral naloxone (exact dose unspecified).

- Oral naloxone alone, either 0.4 or 1.0 mg, produced significant analgesic effects compared with placebo for postoperative dental pain in a trial of 90 patients. In a second trial, oral naloxone (0.4 mg) plus pentazocine (60 mg, a mixed agonist-antagonist opioid) produced greater dental-pain relief than monotherapy with pentazocine (60 mg) or morphine (15 mg). However, naloxone (0.4 mg) plus morphine (8 mg) produced less analgesia than morphine (8 mg) alone, suggesting

---

*On rare occasions, nausea, vomiting, hypertension, pulmonary edema, tachycardia, arrhythmia, and cardiac arrest have been implicated with naloxone doses as small as 0.1-0.4 mg [Pallasch and Gill 1981, Partridge and Ward 1986].

*In most of the literature, ultralow-dose applications of antagonists are usually expressed in microgram amounts. However, since the more well-known applications of naloxone and naltrexone are in milligram increments, doses in this paper are converted from micrograms to milligrams (1 mcg = .001 mg).
that analgesia augmentation by naloxone is influenced by the type and dose of opioid [Levine et al. 1988].

- In a study involving postoperative IV PCA (patient-controlled analgesia), 60 patients received morphone under patient control, plus either placebo or naloxone — 0.00025 mg/kg/h or 0.001 mg/kg/h — via steady IV infusion. Good pain relief was experienced in all groups; however, side effects (nausea, vomiting, pruritus) were reduced by naloxone at either dose and consumption of PCA morphone was significantly reduced by the lowest naloxone dose, suggesting a morphine-enhancement effect of the antagonist [Gan et al. 1997].

- Other postoperative trials compared IV PCA morphone alone versus IV PCA morphone plus an IV naloxone bolus (0.8 mg) administered with each morphone dose (which was equivalent to 0.38 mg/kg/hr of naloxone on average). In the 92 patients studied, investigators found no differences between groups in pain relief, side effects, or morphone consumption [Sartain et al. 2003]. Comparing this study with the Gan et al. [1997] trial above suggests that a continuous naloxone infusion rather than bolus, and at doses of naloxone that are less than in this study, may be required to accrue beneficial effects during naloxone/morphone PCA.

- A more recently reported case series, incorporating intravenous nalbuphine (5 mg) plus naloxone (0.2 mg IV), used postoperatively in 4 women undergoing outpatient gynecological procedures, found improved analgesia with this mixture [Gordon et al. 2007].

- In a case report, a patient with chronic refractory pain following laminectomy was treated with an intrathecal combination of morphone (2 mg) and ultralow-dose naloxone (.000020 mg; that is, 20 nanograms). Dramatic pain relief began within 20 minutes, peaked at 1 hour, and persisted with repeated infusions. Up to 80% improvement was reported by the patient while receiving an intrathecal infusion of 5 mg morphone plus .000050 mg naloxone daily during a 3-year followup period [Hamann et al. 2008].

The trials in postoperative patients suggest that combining low-dose naloxone with opioid agonists can be safe and enhance effectiveness of the analgesic. PCA-based studies further suggest that the augmentation of opioid-agonist effects during PCA is best with sustained ultralow-level antagonism of opioid receptors versus the more complete and intermittent blockade of those receptors by a somewhat higher dose of naloxone [Sloan and Hamann 2006].

**Naloxone for Opioid-induced Constipation**

Another proposed application of low-dose opioid antagonists has been to help prevent or relieve opioid-induced constipation that can be a problematic side effect of long-term opioid analgesics. Meissner et al. [2009] recently reported a clinical trial in 202 patients receiving oxycodone for chronic noncancer pain. Subjects administered 40, 60, or 80 mg/day of extended-release oxycodone were randomized to also receive either 10, 20, or 40 mg/day of extended-release oral naloxone or placebo.

There was no loss of oxycodone analgesic efficacy in patients administered naloxone at any of these higher doses, probably due to naloxone’s limited oral bioavailability. However, bowel function significantly improved with increasing naloxone dose, and there were no unexpected adverse events. A 2:1 dose ratio of oxycodone/naloxone was judged as most efficacious. Other large, randomized, placebo-controlled trials had found the same favorable results in patients with chronic noncancer pain and back pain [Simpson et al. 2008; Vondrackova et al. 2008]. A combination product — using extended-release oxycodone and extended-release
naloxone; 2:1 ratio — was recently approved for marketing in Europe under the name Targin®, with an emphasis on its benefits for providing equipotent oxycodone analgesia while ameliorating opioid-induced constipation [Targin 2009]. Also see Box.

Applications of Naltrexone in Pain Management

As a longer-acting, orally-bioavailable antagonist, naltrexone is easy to administer and may offer advantages over naloxone. In opioid-tolerant animals, naltrexone was shown to produce increased response to morphine [Gonzales and Brogden 1988], possibly by upregulating the opioid-receptor system [Crabtree 1984]. Also of interest, animal experiments suggest that very low doses of naltrexone appear to enhance opioid analgesia to a greater extent when the amount of opioid drug is actually reduced [Crain and Shen 2000b, 2001], which proposes an opioid-sparing effect in humans. A number of investigations in human subjects have explored the potential of low- or ultralow-dose naltrexone as an opioid adjuvant and as monotherapy for the management of several pain-related conditions.

Crohn’s Disease

In 2007, successful results of the first clinical trial of low-dose naltrexone for active Crohn’s disease were published by investigators at the Pennsylvania State University College of Medicine [Smith et al. 2007]. In an open-label study, 17 patients were administered low-dose oral naltrexone (4.5 mg/day at bedtime) for 12 weeks. Statistically significant improvements were found in CDAI (Crohn’s Disease Activity Index) scores and quality of life indicators, increased rates of remission, and decreases in inflammatory markers in serum. Overall, 89% of patients exhibited a favorable response to naltrexone therapy, 67% achieved remission, and 2 subjects with open fistulas had closure. Side effects of therapy were reportedly minimal, with sleep disturbances in 7 patients most common. Reportedly, the National Institutes of Health has granted funding for this same group of researchers to conduct a larger placebo-controlled trial.

Irritable Bowel Syndrome

Kariv et al. [2006] reported an open-label pilot study of ultralow-dose naltrexone (0.5 mg/day) in 42 patients with confirmed irritable bowel syndrome (IBS). During 4 weeks of treatment and 4 weeks of followup, global assessments of symptom relief improved in about three-quarters of the subjects (76%) and mean numbers of pain-free days per week were modestly but significantly increased from baseline. Naltrexone therapy was well tolerated, without any significant adverse reactions.
Despite this initial success, a large, Phase III multi-center, randomized, placebo-controlled trial of oral naltrexone for treating IBS in 600 women was discontinued early due to unacceptable outcomes [Pain Therapeutics 2005]. Naltrexone demonstrated a favorable safety profile, and patients reported statistically meaningful relief of painful IBS symptoms during the second month of treatment compared with placebo. However, these beneficial effects did not persist into the third month, which was the primary endpoint of interest. Possibly, a critical factor was that this trial (and the one by Kariv et al. above) used 0.5 mg/day of naltrexone, which is well below the 4.5 mg every night that others have recommended as monotherapy [described at LDNinfo.org 2009; Smith et al. 2007; also see, fibromyalgia, below].

**Fibromyalgia**

Low-dose naltrexone (LDN) has been purportedly used off-label for the treatment of fibromyalgia for some time, and a small clinical study (n=10) funded by the American Fibromyalgia Syndrome Association (AFSA) was conducted in 2007 at the Stanford University Systems Neuroscience and Pain Lab [SNAPL 2008]. Details and results of this single-blind trial of LDN for the treatment of fibromyalgia have not been published (as of February 2009), but according to some reports the outcomes were successful and the majority of study participants asked to continue on drug therapy after the conclusion of the study [4.5 mg/day oral naltrexone, per correspondence with researcher S. Mackey, 1/28/09]. Side-effects were essentially nonexistent, except for 3 reports of mild sleep disturbance [also see, LDN for Fibromyalgia 2009].

Enrollment is ongoing, as of January 2009, for a large double-blind, placebo-controlled trial of LDN for fibromyalgia [ClinicalTrials.gov 2008]. While the exact mechanisms of naltrexone benefits for fibromyalgia are unknown, the researchers suggest it is possible that low doses of the drug block receptors on glial cells that are responsible for fibromyalgia symptoms [SNAPL 2008]. Previously, *in vitro* experiments on tissue cultures had shown that very low concentrations of opioid antagonists stimulated nerve tissue growth and the response of certain nerve tissues to the favorable effects of endogenous opioid peptides [Ilyinsky et al. 1987]. Hypothetically at least, these combined effects may play a role in the rejuvenation of nerve tissues that become sensitized or deranged in fibromyalgia syndrome.

More recently, neuroimaging studies (via positron emission tomography or PET) found that patients with fibromyalgia had significantly reduced availability of mu-opioid receptors in specific brain regions known to modulate pain, as compared with healthy control subjects [Harris et al. 2007]. The investigators suggested this as a possible explanation for why exogenous opioids generally have reduced effectiveness in fibromyalgia. Low-dose naltrexone, by upregulating the opioid-receptor system, might increase the body's responsiveness to endogenous opioid peptides in helping to relieve fibromyalgia pain. Whether or not adjuvant LDN therapy also could improve patient response to exogenous opioid analgesics has not been reported.

**Neuropathic Pain**

Recently reported laboratory experiments, and a case example, suggest benefits of opioid antagonists in ameliorating neuropathic pain. Prior investigations demonstrated that activated spinal cord glial cells (microglia and astrocytes) contribute importantly to neuropathic pain; although, how nerve irritation or injury activate glia is still undefined. In rodents, Hutchinson et al. [2008] found that isomers of naloxone and naltrexone can suppress microglial activation and aid in reversing neuropathic pain. Similarly, investigators recently described analgesic enhancement by an oxycodone/ultralow-dose naltrexone combination administered orally or spinally in a rodent model of neuropathic pain [Largent-Milnes et al. 2008].

*The potential for ultralow-dose naltrexone to benefit neuropathic pain conditions needs further exploration.*
Other positive effects on nerve tissues had been reported much earlier by Ilvinsky and colleagues [1987, described above].

There has been at least one case report of positive effects of antagonists for reducing neuropathy in humans. Cruciani et al. [2003] described a patient with chronic painful diabetic neuropathy being treated unsuccessfully with methadone. The addition of ultralow-dose oral naltrexone (0.002 mg/day) dramatically improved pain relief and, at the same time, allowed a 16% reduction in methadone dose.

Based on laboratory experiments and the very limited clinical evidence, low- or ultralow-dose naltrexone might potentially benefit reflex sympathetic dystrophy (RSD, also known as complex regional pain syndrome or CRPS). However, this has not been reported in the literature, and the role of the nervous system in this syndrome and its appropriateness as a target for treatment require further definition [Bennett and Brookoff 2006].

Naltrexone Combined with Opioid Agonists

Successful Phase II [Chindalore et al. 2005] and Phase III [Webster et al. 2006] trials have been completed on a combination oxycodone plus ultralow-dose naltrexone product. In the first trial, 243 patients with chronic, painful osteoarthritis were administered placebo, oxycodone QID (4x/day), or oxycodone + 0.001 mg naltrexone (Oxytrex™) either QID or BID (2x/day) [Chindalore et al. 2005]. The total daily oxycodone dose (titrated up to 80 mg/day or less) was the same in all treatment groups on average, but the Oxytrex groups additionally received either 0.002 or 0.004 mg naltrexone per day. Oxytrex BID (ie, oxycodone + 0.002 mg/day naltrexone) provided significantly superior pain relief compared with oxycodone alone QID, Oxytrex QID, or placebo.

The Phase III trial enrolled 719 patients with chronic back pain using essentially the same treatment protocol as above [Webster et al. 2006]. All active-treatment groups achieved comparable pain relief, although the addition of naltrexone in Oxytrex allowed significantly lower consumption of that combination drug than with oxycodone alone. Patients receiving Oxytrex BID also experienced significantly less constipation, somnolence, and/or pruritus than subjects in the other active-treatment groups.

The potential benefits of such agonist/antagonist combinations seems promising; however, this may depend on the type of opioid and/or the naltrexone dose. In an experimental trial in healthy humans, using a thermal discomfort test, the addition of 0.25, 0.5, or 1.0 mg of oral naltrexone neither aided nor deterred analgesic effects of oral hydrocodone [Cantilena et al. 2004]. These findings are very preliminary, and the naltrexone doses in this study were many-fold larger than in the Oxytrex formulation, so further research on combination products seems warranted.

Hamann and Sloan [2007] reported a clinical pilot study to assess the analgesic efficacy of ultralow-dose oral naltrexone combined with intrathecal morphine infusions in patients with chronic, refractory nonmalignant pain. Subjects being administered continuous intrathecal morphine were randomized in double-blind fashion to receive either oral placebo (n=5) or oral naltrexone — 0.1 mg (n=3) or 0.01 mg (n=7) — every 12 hours for 7 days. The group receiving 0.1 mg BID (0.2 mg/day total) of adjuvant naltrexone exhibited significant reductions in pain intensity and greater pain relief compared with placebo; whereas, the 0.01 mg BID naltrexone dose (0.02 mg/day total) was ineffective. There were no serious adverse events or evidence of opioid withdrawal, and side effects were minor and similar across all treatment groups (eg, headache, nausea, sedation, dry mouth).
Aid for Opioid Tapering

Another interesting application has been the use of very low doses of naltrexone to diminish withdrawal signs/symptoms in patients being tapered from long-term opioid therapy. Mannelli et al. [2006] describe a study in methadone-maintained patients administered ultralow-dose oral naltrexone (0.125 – 0.250 mg/dose) during inpatient opioid detoxification. Overall signs of withdrawal were repressed, even as naltrexone doses were increased daily, and the opioid-tapering process was completed without adverse incidents or patient discomfort.

A larger (n=174), randomized, placebo-controlled study by this group [Mannelli et al. 2008], found similar benefits of ultralow-dose oral naltrexone (0.125 mg or 0.250 mg/dose) combined with tapered methadone doses during a 6-day outpatient detoxification protocol. Naltrexone-treated patients experienced milder withdrawal symptoms and reduced opioid craving compared with placebo-group subjects. There were no treatment-related adverse events reported.

Extensions of LDN Theory & Application

Besides the potential advantages of opioid antagonists for pain management described above, off-label low-dose naltrexone (LDN) protocols have been reported as benefitting a number of important immunological and neurological disorders. This is believed due at least in part to the observation that many body tissues, including virtually every cell of the body’s immune system, have receptors that are routinely stimulated by endogenous opioid peptides — including endorphins and enkephalins [Machelska and Stein 2002]. Therefore, by acting at those receptors, LDN has been demonstrated as possibly having important capabilities to modulate the immune system and promote healing [LDNinfo.org 2009; NCI 2007].

Therapeutic implications of LDN date back to the mid-1980s when researcher Bernard Bihari, MD, in New York discovered its beneficial effects in the newly emerging disease of HIV/AIDS [reported in NCI 2007]. In subsequent years, Bihari found that LDN appeared to stem the progress of every autoimmune disease in which it was tested. The agent also has been attributed as benefitting a long list of neurodegenerative and other disorders, many of which have pain as a significant symptom, including Parkinson’s disease, amyotrophic lateral sclerosis (ALS), and primary progressive multiple sclerosis [Gironi et al. 2008].

In very limited clinical investigations, LDN has been shown to halt disease progression in certain cancers and to reduce symptoms of autism [LDNinfo.org 2009]. Some authors have recently suggested that, since LDN can upregulate endogenous opioid activity, it may have a role in promoting stress resilience and emotional well-being, as well as the amelioration of depression [Brown and Panksepp 2008].

The typical therapeutic dosage range for LDN in these applications is from 1.75 mg to 4.5 mg taken at bedtime. It has been suggested that doses below this range are likely to have little effect for neurodegenerative and other disorders, while doses above this range could block endogenous opioid peptides for too long a period of time and interfere with naltrexone’s effectiveness [LDNinfo.org 2009].

The actions of low-dose naltrexone on endogenous-opioid receptors, may have important capabilities for modulating the immune system and promoting healing in various immunological and neurological disorders.
Prescribing Opioid Antagonists

Opioid antagonists are non-scheduled drugs that may be prescribed by any appropriately licensed healthcare provider. However, low- or ultralow-dose formulations of naloxone and naltrexone are not commercially available and must be specially compounded by pharmacies equipped for this purpose.

The website, LDNinfo.org, under the editorial direction of David Gluck, MD, provides recommendations regarding the ordering of low-dose naltrexone [LDNinfo.org 2009]. Apparently, low-dose naltrexone prescriptions in 1 mg to 5 mg doses are being filled by many local and mail order pharmacies, and Gluck notes that a 30-day supply of 4.5 mg naltrexone capsules may cost from $15 to $38 (USD).

He specifies that pharmacies should be instructed to not provide naltrexone in slow-release (SR) or timed-release form. Furthermore, calcium carbonate fillers should not be employed in compounding capsules because they may interfere with naltrexone absorption.

The website also cautions that it is important that the compounding pharmacy has a reputation for consistent reliability in the quality and accuracy of opioid antagonist preparations that it delivers.* In one investigation, the FDA found significant error rates in compounded prescriptions produced at randomly selected pharmacies. More than a third (34%) of sampled products failed one or more standard quality tests performed by the FDA, including inadequate potency in 90% of the failing products [FDA/CDER 2003].

Recommendations are lacking regarding where to order naloxone or naltrexone in ultralow, microgram doses (<1.0 mg). However, contacts with several compounding pharmacies confirm that both naltrexone and naloxone powders are readily available and most of those pharmacies are well-equipped to prepare doses in any amounts specified [author’s correspondence during January 2009]. Presumably, the same cautions as above would apply to ultralow-dose formulations; ie, avoidance of slow-release formulations and calcium carbonate fillers.

Summary & Conclusions

Select applications of naloxone and naltrexone may offer novel and potentially effective approaches for resolving difficult pain management challenges. Table 2 on the next page briefly summarizes the applications, doses, and outcomes in research on adult human subjects that were described in more detail above.

Both of these agents have passed animal and clinical toxicity studies, and are FDA-approved for applications other than those described in this paper. Therefore, it is not surprising that they have exhibited favorable safety profiles when applied at low- and ultralow-dose levels, with few if any reports of adverse events or side effects at these doses when used individually as monotherapy or in combination with opioid analgesics.
Explanatory mechanisms of action behind the benefits of opioid antagonists in pain management are still under investigation. A significant body of laboratory research, in animals or tissue cultures, suggests that the opioid-receptor system is very complex, affecting a variety of tissue and cell types, and with functions extending beyond antinociception (i.e., pain-relief). It appears that blockade of opioid receptors exerted by very small concentrations of naloxone or naltrexone may stimulate a cascade of actions at the cellular and molecular levels that may contribute to their multiple beneficial effects. Some of those proposed actions were briefly de-

scribed in this paper.

For the most part, clinical research to date on low- or ultralow doses of opioid antagonists in humans has been limited. Except for several larger, controlled trials, reports in the literature have included small numbers of patients or represented case examples. Collectively, the research appears to offer some suggestions for the application and dosing of naloxone or naltrexone, but there are no well-established or standardized protocols when it comes to their use in pain management. Still, the available evidence, as summarized in Table 2, does propose a number of general possibilities that may be of interest to pain practitioners and their adult patients:

1. Brief detoxification via IV naloxone for difficult cases of opioid-unresponsive intractable pain, opioid tolerance, or suspected opioid-induced hyperalgesia.

2. Ultralow-dose oral naloxone combined with various opioid agonists for managing acute postoperative pain.

3. Adjuvant ultralow-dose naloxone (continuous IV infusion) combined with patient controlled analgesia (PCA) postoperatively.

4. Ultralow-dose naltrexone (oral) or naloxone (intrathecal) as a component of intrathecal opioid analgesia for difficult cases of intractable pain.

5. Ultralow-dose naltrexone combined with opioid agonists to provide an opioid-sparing effect, offering equivalent pain relief at lower opioid doses.

6. Oral ultra-low dose naloxone or naltrexone combined with oral opioid analgesics to help prevent or reverse opioid-induced constipation and potentially ameliorate other opioid side effects.

7. Ultralow-dose naltrexone to help facilitate more comfortable opioid-agonist tapering.

Certainly, further research, including large-scale clinical trials, are needed to better understand the capabilities and safety of opioid antagonists for treating pain conditions of various types. Meanwhile, healthcare providers interested in using low- or ultralow-dose naloxone or naltrexone would need to cautiously prescribe these agents off-label for compounding at properly equipped pharmacies.

Clearly, the type of antagonist (naloxone or naltrexone), mode of administration (oral, IV, IT), the dose (low or ultralow), the pain disorder being treated, comorbidities, and concurrent opioid analgesia can all interact to make important differences. For example, the first commercial agonist/antagonist combination products — Targin, approved in Europe, and Oxytrex, in development — have used vastly differing doses of either naloxone or naltrexone, respectively, due to the dissimilar oral bioavailabilities of the two antagonists.

Hopefully, other opioid analgesics incorporating naloxone or naltrexone for pain management applications will be formally tested and developed. Whether or not sponsors will come forward to initiate the necessary but costly clinical trials and seek appropriate regulatory-agency approvals remains to be seen.

As monotherapy, the development of FDA-approved formulations of low- and ultralow-dose naloxone or naltrexone used alone for pain management purposes may face some formidable hurdles. For example, at a U.S. government-sponsored conference [NCI 2007], it was noted
that, “[Low-dose naltrexone] has been presented to big pharmaceutical companies, but there has been little support provided, as LDN is commercially available and it is unclear whether or not there could be patent coverage for a new indication at [the very low dosages].”

In sum, the opioid antagonists naloxone and naltrexone appear to offer promise for helping to achieve more effective pain management in some of the most difficult and challenging situations facing healthcare providers and their adult patients. These agents are available today and, although they are approved for other applications, it is important that practitioners become aware of the therapeutic options that these agents may provide for patient care.

About the Author

Stewart B. Leavitt, MA, PhD is the founding Publisher/Editor-in-Chief of Pain Treatment Topics and has more than 25 years of experience in healthcare education and medical communications serving numerous government agencies, pharmaceutical companies, and private organizations. He was educated in biomedical communications at the University of Illinois at Chicago College of Medicine and then served as a Commissioned Officer in the US Public Health Service at the National Institutes of Health, Clinical Center, Bethesda, Maryland. He went on to earn Masters and Doctorate degrees specializing in health/medical education at Northwestern University, Evanston, Illinois, where he also was an instructor and a Ford Fellow researching urban healthcare delivery systems. He is a member of the American Academy of Pain Management and a founding member of the International Association for Pain & Chemical Dependency.

Report Reviewers

Pain Treatment Topics acknowledges and thanks the following professionals for their expert reviews and assistance:

- **Jeffrey Fudin, BS, PharmD, DAAPM** — Clinical Pharmacy Specialist, Pain Management, VAMC Albany; Adjunct Associate Professor of Pharmacy Practice, Albany College of Pharmacy & Health Sciences; and, Diplomate, American Academy of Pain Management.

- **Edward Hesterlee, PharmD** — Associate Professor of Pharmacy Practice, University of Arkansas Medical Sciences (UAMS) College of Pharmacy, Little Rock, AR, and a consultant to the pharmaceutical industry and national pharmacy associations.

- **Seth I. Kaufman, MD** — Pain management and palliative care practitioner, West Clinic, Baptist Hospital, and Methodist Hospital, Memphis, TN.

- **Lee A. Kral, PharmD, BCPS** — Faculty member, Center for Pain Medicine and Regional Anesthesia, University of Iowa Hospitals and Clinics, Iowa City, IA.

- **James D. Toombs, MD** — Staff physician, Division of Primary Care/Pain Medicine, Harry S. Truman Memorial Veterans' Hospital, Columbia, MO.
