Key words: melanoma, photodynamic therapy, indocyanine green

Spectroscopic, photochemical and biological properties of indocyanine green (ICG) are presented. Light over 800 nm is effectively absorbed by ICG. This property as well as photochemical behaviour of ICG make it a very suitable dye for photodynamic treatment of melanoma cells. Cytotoxicity of ICG itself and the effect of photodynamic therapy (PDT) were evaluated by following the growth of human (SKMEL 188) and mouse (S91) melanoma cells. The surviving fraction of the cells irradiated ($\lambda_{\text{ex}} = 830$ nm) vs non-irradiated, treated with the same dose of ICG, is significantly decreased (5- to 10-fold). These results show that ICG is a very promising dye for photodynamic therapy of melanomas.

The use of photosensitizers coupled with light irradiation is a widely studied method (photodynamic therapy, PDT) in the treatment of a great variety of malignant tumours (Baumler *et al.*, 1999). Poor therapeutic results were reported for pigmented human melanoma (Dougherty, 1987; Zhou, 1992) and for

experimental melanoma (Kukielczak *et al.*, 1995). This might be explained by a high content of melanin, which can act as a screen for white light (Chedekel, 1995). A good photosensitizer for melanomas must selectively photodamage the tumour tissue when irradiated with visible or preferably near infrared

Abbreviations: ICG, indocyanine green; NaCl/P_i buffer; PDT, photodynamic therapy.

light. In this contribution we describe a new potential photosensitizer for PDT, indocyanine green (ICG).

ICG, commonly used as an angiographic agent, has a very interesting photochemical property: it has a strong absorption between 700–800 nm (Baumler *et al.*, 1999). It is known that melanins practically do not absorb in this area (Chedekel, 1995). On the other hand, the near infrared light is characterized by a deep penetration into tissues (Wilson *et al.*, 1985).

Considering these facts, it was tempting to examine the influence of the ICG-mediated PDT of human (SKMEL 188) and mouse (S91) melanoma cells *in vitro*. Some photochemical properties of the compound were also tested to explain the mechanism of ICG action.

MATERIALS AND METHODS

Chemicals. ICG obtained from Sigma was used for spectrophotometric measurements and ICG-Pulsion (PULSION Verwaltungs GmbH & Co., Munich, Germany) was used for bioassays.

Instrumental. Absorption was measured using the Hewlett Packard 8453 diode array spectrophotometer.

Photobleaching experiments were carried out in a special 1 cm black quartz cell with a transparent hole (to eliminate diffusion artifacts), connected to a diode laser equipped with a fibre optical connector. The laser emission of 830 nm was used.

Bioassays

Cytotoxicity assay. To check the cytotoxicity of ICG on human melanoma cells (SKMEL 188) and mouse melanoma cells (S91), the cells were incubated for 4 h in NaCl/P_i buffer containing different concentrations of the dye (10–250 μ M). Thereafter the cells were maintained in the culture medium: F10 with 10% serum (SKMEL) and

RPMI with 5% serum (S91) for 48 h. The cytotoxicity in the dark was monitored by counting the number of untreated and ICG treated cells.

Photodynamic effect measurements. To evaluate the influence of the ICG-based PDT on cell growth, the investigated cells were irradiated using a diode laser (MC LASER, therapy laser processor PMC-018, Katowice, Poland). All irradiations were performed at $\lambda_{\text{ex}} = 830$ nm and at a fluence rate of 100 or 200 mW/cm² with the doses from 30 to 100 J/cm² in the presence of the photosensitizer (100 μ M). After irradiation the cells were incubated in the culture medium for 48 h. Surviving cells were monitored by counting the number of untreated and PDT treated cells.

RESULTS AND DISCUSSION

Figure 1 presents the chemical structure of indocyanine green (ICG). The ICG optical spectrum consists of two main peaks, at 778 nm and at 708 nm (Fig. 2). The shape of the absorption curve fits well to the Gaussian curves peaked at the absorption maxima (not shown). The absorption maxima refer to two forms of the dye, the monomeric form (778 nm) with a molar absorption coefficient of 10800 M⁻¹cm⁻¹ and an oligomeric form (708 nm). It seems that the tetrameric form is dominating (Zhou *et al.*, 1994). The equilibrium between the forms depends on several factors such as dye concentration (Fig. 2), nature of the solvent, ionic strength, pH and temperature (not shown). With increasing concentration of ICG, the content of monomeric form decreases and the absorption is shifted towards shorter wavelengths. This fact reflects an increase in the amount of oligomeric forms in solution. Also a rise in ionic strength may change the ratio between monomers and n-mers in the system, increasing the aggregation rate (Landsman *et al.*, 1976). Considering that ICG itself is practically insoluble in phosphate buffer, we dis-

solved the dye first in water and then added the prepared ICG solution to NaCl/P_i buffer. The n-mer forms of ICG were dominant in the final solution (Fig. 3).

ICG solutions are not stable (Landsman *et al.*, 1976; Zhou *et al.*, 1994). After a few days a new peak with a maximum near 900 nm appears (inset in Fig. 2, curve D), probably due

SKMEL cells are a little pigmented in the spectral region but beyond ICG absorption.

to degradation and further polymerization. This is connected with the formation of so called J-aggregate (Weigand *et al.*, 1997). Degradation depends on many factors like the degree of aggregation, illumination, kind of solvent and oxygen concentration (Zhou *et al.*, 1994).

We observed photobleaching as early as after 3 min of irradiation under conditions comparable to those used in the PDT assay (Fig. 3). The decrease in intensity was similar for both peaks of absorption. After 25 min the absorption was about 4 times lower (inset in Fig. 3).

ICG essentially absorbs in the near infrared part of the spectrum, and this fact is important for melanoma treatment, because melanins practically do not absorb in this wavelength area (Fig. 4).

ICG-based PDT is presented in Fig. 5. The photosensitizing efficiency of ICG was very high for melanoma cells. The surviving fraction of the irradiated cells decreased more than 10-fold (for 100 J/cm^2 with the fluence rate of 200 mW/cm^2) compared with non-irradiated cells. Dark toxicity of ICG on SKMEL 188 and S91 melanoma cells was also investigated. At the tested concentrations of the dye survival of the cells was the same.

Near infrared absorbing compounds are ideal for treatment of melanomas because light in this range is not absorbed by

Cells were treated with ICG ($100 \mu\text{M}$), illuminated with indicated fluence (mW/cm^2) and further incubated in growth medium in the dark for 48 h.

melanins. Additionally, increased depth of penetration due to longer wavelength enhances treatment effectiveness. The clinically approved dye indocyanine green is a promising photosensitizer in the light of our *in vitro* data, but needs further investigation under *in vivo* conditions.
